Randomized Kinodynamic Planning for Constrained Systems

Ricard Bordalba, Lluís Ros, and Josep M. Porta

Abstract—Kinodynamic RRT planners are considered to be general tools for effectively finding feasible trajectories for high-dimensional dynamical systems. However, they struggle when holonomic constraints are present in the system, such as those arising in parallel manipulators, in robots that cooperate to fulfill a given task, or in situations involving contacts with the environment. In such cases, the state space becomes an implicitly-defined manifold, which makes the diffusion heuristic inefficient and leads to inaccurate dynamical simulations. To address these issues, this paper presents an extension of the kinodynamic RRT planner that constructs an atlas of the state-space manifold incrementally, and uses this atlas both to generate random states and to dynamically steer the system towards such states. To the best of our knowledge, this is the first randomized kinodynamic planner that explicitly takes holonomic constraints into account. We validate the approach in significantly-complex systems.

I. INTRODUCTION

The motion planning problem has been a subject of active research since the early days of robotics [1]. Although it can be formulated in simple terms—find a feasible trajectory to move a robot between two states—and despite the significant advances in the field, it is still an open problem in many respects. The complexity of the problem arises from the multiple constraints that have to be taken into account, like potential collisions with static or moving objects in the environment, loop-closure constraints, dynamic equations, torque and velocity limits, or energy and time execution bounds, to name a few. Often, such a complexity is managed by relaxing some of the constraints. For example, while obstacle avoidance is a fundamental issue, lazy approaches initially disregard it [2]. Other approaches concentrate on kinematic feasibility [3], which is already a challenging issue by itself. In these and other approaches, dynamic constraints such as speed, acceleration, or torque limits are neglected, with the hope that they will be enforced in a post-processing stage, using dynamic time-scaling methods for example [4]. Decoupled approaches, however, may not lead to solutions satisfying all the constraints. It is not difficult to find situations in which a kinematically-feasible path cannot be transformed into a time-parametric trajectory compatible with the system dynamics. For this reason, substantial efforts have also been devoted to obtaining so-called kinodynamic planners, which directly synthesize state trajectories simultaneously compatible with as many kinematic and dynamic constraints as possible [5], [6], [7], [8].

Among all kinodynamic planning approaches, the rapidly-exploring random tree (RRT) method [6] has emerged as one of the most successful algorithms. Kinodynamic RRT planners are conceptually simple, easy to implement, and effective, even in high dimensions. Often, such planners are thought to be quite general, being able to accommodate most of the motion planning constraints needed in practice. While it is true that kinodynamic RRTs cover many situations, they suffer from an important limitation: they assume that the state space can be described parametrically, or, in other words, that the robot state can be represented by means of independent generalized coordinates. Although parametric state spaces arise frequently, for example in single-body robots, or in articulated robots with tree topology, holonomic constraints may also appear that relate the state space coordinates in nontrivial ways. This occurs, for example, in systems with closed kinematic chains, in robots in contact with the environment, or when geometric constraints are needed to fulfill a given task. In these cases, the robotic system is said to be constrained, because its state space is a manifold implicitly-defined by a system of nonlinear equations.

Standard kinodynamic RRT methods are in trouble on constrained systems: their diffusion heuristic becomes inefficient, they may fail to find feasible motions when they exist, and easily produce simulations that violate the holonomic constraints. A goal of this paper is to show that these difficulties can all be circumvented if the differential geometric structure of the state space is considered inside the planner. While some approaches treat holonomic constraints [9], [10], [11], [12], [13], [14], none of them considers the dynamics of the system into the planner. This paper extends the methods in [14] to obtain a randomized kinodynamic planner that simultaneously enforces holonomic and dynamic constraints. This planner can also be seen as an extension of the one in [6] to deal with holonomic constraints.

The rest of the paper is organized as follows. Section II formulates the motion planning problem on constrained robotic systems with dynamic constraints. Then, Section III illustrates the mentioned difficulties of the classic kinodynamic RRT method [6] when applied to such systems. Sections IV and V show how this method can be duly extended to overcome these difficulties. The idea is to construct an atlas of the state space incrementally, and then use this atlas to efficiently push the growing of the tree towards unexplored regions, while at the same time performing accurate dynamic simulations. The planner is validated on a number of test cases in Section VI, and Section VII finally concludes the paper, discussing points for further attention.
II. PROBLEM FORMULATION

Let us describe a robot configuration by means of a tuple \( \mathbf{q} \) of \( n_q \) generalized coordinates, which determine the positions and orientations of all links at a given instant of time. We restrict our attention to constrained systems, i.e., those in which \( \mathbf{q} \) must satisfy a system of \( n_e \) nonlinear equations

\[
\Phi(\mathbf{q}) = 0
\] (1)

encompassing all holonomic constraints to be taken into account, either inherent to the robot design (like closed kinematic chains) or necessary for task execution (like geometric or contact constraints imposed on the end-effector). Then, the configuration space \( \mathcal{C} \) of the robot, or \( C \)-space for short, is the nonlinear variety \( \mathcal{C} = \{ \mathbf{q} : \Phi(\mathbf{q}) = 0 \} \), which may be quite complex in general. Under mild conditions, however, we can assume that the Jacobian \( \Phi_q(\mathbf{q}) \) is full rank for all \( \mathbf{q} \in \mathcal{C} \), so that \( \mathcal{C} \) is a smooth manifold of dimension \( d_C = n_q - n_e \). By differentiating Eq. (1) with respect to time we obtain

\[
\Phi_q(\mathbf{q}) \dot{\mathbf{q}} = 0.
\] (2)

which delimits the feasible velocity vectors \( \dot{\mathbf{q}} \) at a given \( \mathbf{q} \in \mathcal{C} \). Now, let \( \mathbf{F}(\mathbf{x}) = \mathbf{0} \) denote the system formed by Eqs. (1) and (2), where \( \mathbf{x} = (\mathbf{q}, \dot{\mathbf{q}}) \in \mathbb{R}^{2n_q} \). While [14] operates in \( \mathcal{C} \), our planning problem will take place in the state space

\[
\mathcal{X} = \{ \mathbf{x} : \mathbf{F}(\mathbf{x}) = \mathbf{0} \}.
\] (3)

Since \( \Phi_q(\mathbf{q}) \) is full rank, \( \mathcal{X} \) is also a smooth manifold of dimension \( d_X = 2d_C \), which implies that the tangent space of \( \mathcal{X} \) at \( \mathbf{x} \),

\[
\mathcal{T}_\mathbf{x}\mathcal{X} = \{ \dot{\mathbf{x}} \in \mathbb{R}^{2n_q} : \mathbf{F}_x(\mathbf{x}) \dot{\mathbf{x}} = \mathbf{0} \},
\] (4)

is well-defined and \( d_X \)-dimensional for any \( \mathbf{x} \in \mathcal{X} \).

We shall encode the forces and torques of the actuators into an action vector \( \mathbf{u} \) of dimension \( n_u \). Given a starting state \( \mathbf{x}_s \in \mathcal{X} \), and the vector \( \mathbf{u} \) as a function of time, \( \mathbf{u} = \mathbf{u}(t) \), the time evolution of the constrained system is determined by a differential-algebraic equation of the form

\[
\begin{align*}
\mathbf{F}(\mathbf{x}) &= \mathbf{0}, \\
\dot{\mathbf{x}} &= \mathbf{g}(\mathbf{x}, \mathbf{u}).
\end{align*}
\] (5)

Eq. (5) forces the states \( \mathbf{x} \) to remain in \( \mathcal{X} \), while Eq. (6) models the dynamics of the system, and can be obtained from the multiplier form of the Euler-Lagrange equations [15]. For each value of \( \mathbf{u} \), Eq. (6) defines a vector field over \( \mathcal{X} \), which can be used together with Eq. (5) to integrate the robot motion forward in time, using proper numerical methods.

To model the fact that the actuator forces are limited in practice, we assume that \( \mathbf{u} \) takes values in some bounded subset \( \mathcal{U} \) of \( \mathbb{R}^{n_u} \), which indirectly limits the acceleration of the system. During its motion, moreover, the robot cannot incur in collisions with itself or with the environment, which reduces the feasible states \( \mathbf{x} \) to those lying in a subset \( \mathcal{X}_\text{free} \subseteq \mathcal{X} \) of non-collision states, which should always fulfill any existing limits on \( \mathbf{q} \) and \( \dot{\mathbf{q}} \).

With the previous definitions, the planning problem we confront can be phrased as follows. Given two states of \( \mathcal{X}_\text{free} \), \( \mathbf{x}_s \) and \( \mathbf{x}_g \), find an action trajectory \( \mathbf{u} = \mathbf{u}(t) \in \mathcal{U} \) such that the trajectory \( \mathbf{x} = \mathbf{x}(t) \) determined by Eqs. (5) and (6) for \( \mathbf{x}(0) = \mathbf{x}_s \) fulfills \( \mathbf{x}(t_f) = \mathbf{x}_g \) for some time \( t_f > 0 \), and \( \mathbf{x}(t) \in \mathcal{X}_\text{free} \) for all \( t \in [0, t_f] \).

III. DRAWBACKS OF THE STANDARD RRT METHOD

Observe from the previous section that, in contrast to [6], we allow the presence of Eq. (1) in the formulation of our planning problem, which makes it more general and challenging at the same time. In the literature, the suggested
way to handle this equation is to differentiate it twice, and use it in conjunction with the Euler-Lagrange equations with multipliers to obtain the explicit form of the motion equation [16, Sec. 13.4.3.1]. In fact, this is the process that we follow to obtain Eq. (6). However, the application of the standard RRT method to this equation alone, disregarding Eq. (5), presents the following drawbacks.

On the one hand, the random samples used to guide the RRT extension would not be generated on \( \mathcal{X} \), but in the larger ambient space \( \mathbb{R}^{2n_q} \), which results in an inefficient exploration of \( \mathcal{X} \) [14], [17]. This can be seen in Fig. 1(a), in which a partial RRT has been grown on \( \mathcal{X} \). Clearly, there is a high probability of producing an ambient space sample \( \mathbf{x}_{\text{rand}} \) such that the nearest RRT node, \( \mathbf{x}_{\text{near}} \), will only be expanded slightly towards a new node \( \mathbf{x}_{\text{new}} \).

On the other hand, note that the standard RRT method would only use Eq. (6) to simulate the motion of the system, treating it as an ordinary differential equation. However, from multibody mechanics it is known that the motion of a constrained system can only be predicted reliably if Eq. (5) is also taken into account during the integration of Eq. (6) [18]. Otherwise, the inevitable errors introduced when discretizing Eq. (6) will make the trajectory \( \mathbf{x}(t) \) increasingly drift away from \( \mathcal{X} \) as the simulation progresses. This phenomenon is shown in Fig. 1(b) for a four-bar pendulum modeling a swing-boat ride. The pendulum has to be moved from the starting to the goal states indicated (points 1 and 2 of \( \mathcal{X} \)) and, as a result, the query states cannot be connected reliably.

IV. MAPPING AND EXPLORING THE STATE SPACE

We will next see that the sampling and drift issues just mentioned can both be circumvented by constructing an atlas of \( \mathcal{X} \). The atlas will provide us with a means to sample the \( \mathcal{X} \) manifold, instead of the larger ambient space. In addition, the atlas charts will permit the integration of Eqs. (5) and (6) as a true differential-algebraic equation, guaranteeing a driftless simulation of the robot motions along the tree branches. These ideas will then be used in Section V to implement an RRT planner for constrained systems.

A. Atlas construction

Formally, an atlas of \( \mathcal{X} \) is a collection of charts mapping \( \mathcal{X} \) entirely, where each chart \( \mathcal{c} \) is a local diffeomorphism \( \varphi_{\mathcal{c}} \) from an open set \( \mathcal{V}_{\mathcal{c}} \subset \mathcal{X} \) to an open set \( \mathcal{P}_{\mathcal{c}} \subset \mathbb{R}^{d_{\mathcal{X}}} \) [Fig. 2(a)]. The \( \mathcal{V}_{\mathcal{c}} \) sets can be thought of as partially-overlapping tiles covering \( \mathcal{X} \), in such a way that every \( \mathbf{x} \in \mathcal{X} \) lies in at least one set \( \mathcal{V}_{\mathcal{c}} \). The point \( \mathbf{y} = \varphi_{\mathcal{c}}(\mathbf{x}) \) provides the local coordinates, or parameters, of \( \mathbf{x} \) in chart \( \mathcal{c} \). Since each map \( \varphi_{\mathcal{c}} \) is a diffeomorphism, its inverse map \( \psi_{\mathcal{c}} = \varphi_{\mathcal{c}}^{-1} \) exists and gives a local parameterization of \( \mathcal{V}_{\mathcal{c}} \).

To construct \( \varphi_{\mathcal{c}} \) and \( \psi_{\mathcal{c}} \), we shall use the so-called tangent space parameterization [15], [19]. In this approach, the map \( \mathbf{y} = \varphi_{\mathcal{c}}(\mathbf{x}) \) around a given \( \mathbf{x}_{\mathcal{c}} \in \mathcal{X} \) is obtained by projecting \( \mathbf{x} \) orthogonally to \( T_{\mathbf{x}} \mathcal{X} \) [Fig. 2(b)]. Thus \( \varphi_{\mathcal{c}} \) becomes

\[
\mathbf{y} = U_{\mathcal{c}}^\top (\mathbf{x} - x_{\mathcal{c}}),
\]

where \( U_{\mathcal{c}} \) is a \( 2n_q \times d_{\mathcal{X}} \) matrix whose columns provide an orthonormal basis of \( T_{\mathbf{x}} \mathcal{X} \). The map \( \mathbf{x} = \psi_{\mathcal{c}}(\mathbf{y}) \) is implicitly determined by the system of nonlinear equations

\[
F(\mathbf{x}) = 0,
\]

\[
U_{\mathcal{c}}^\top (\mathbf{x} - x_{\mathcal{c}}) - \mathbf{y} = 0,
\]

which, for a given \( \mathbf{y} \), can be solved for \( \mathbf{x} \) using the Newton-Raphson method (if \( \mathbf{x} \) is close to \( x_{\mathcal{c}} \)).

Assuming that an atlas has been, the problem of sampling \( \mathcal{X} \) boils down to sampling the \( \mathcal{P}_{\mathcal{c}} \) sets, since the \( \mathbf{y} \) values can always be projected to \( \mathcal{X} \) using the map \( \mathbf{x} = \psi_{\mathcal{c}}(\mathbf{y}) \). Also, the atlas allows the conversion of the vector field defined by Eq. (6) into one in the coordinate spaces \( \mathcal{P}_{\mathcal{c}} \). The time derivative of Eq. (7), \( \dot{\mathbf{y}} = U_{\mathcal{c}}^\top \dot{\mathbf{x}} \), gives the relationship between the two vector fields, and allows writing

\[
\dot{\mathbf{y}} = U_{\mathcal{c}}^\top \mathbf{g}(\psi_{\mathcal{c}}(\mathbf{y}), \mathbf{u}),
\]

which is Eq. (6), but expressed in local coordinates. This equation still takes the full dynamics into account, and forms the basis of the so-called tangent-space parameterization methods for the integration of differential-algebraic equations [20]. Given a state \( \mathbf{x}_k \) and an action \( \mathbf{u} \), \( \mathbf{x}_{k+1} \) is estimated by obtaining \( \mathbf{y}_k = \varphi_{\mathcal{c}}(\mathbf{x}_k) \), then computing \( \mathbf{y}_{k+1} \) using a
discrete form of Eq. (9), and finally getting \( x_{k+1} = \psi_r(y_{k+1}) \). The procedure guarantees that \( x_{k+1} \in \mathcal{X} \) by construction, which makes the integration compliant with all kinematic constraints in Eq. (5).

**B. Incremental atlas and RRT expansion**

One could build a full atlas of the implicitly-defined state space and then use its local parameterizations to define a kinodynamic RRT. However, the construction of a full atlas is only feasible for low-dimensional state spaces. On the other hand, only part of the atlas is necessary to solve a given motion planning problem. Thus, a better alternative is to combine the construction of the atlas and the expansion of the RRT [14]. In this approach, a partial atlas is used to both generate random states and grow the RRT branches. Also, as described next, new charts are created as the RRT branches reach unexplored areas of the state space.

Suppose that \( x_k \) and \( x_{k+1} \) are two consecutive steps along an RRT branch, whose parameters in the chart defined at \( x_c \) are \( y_k \) and \( y_{k+1} \), respectively. Then, a new chart at \( x_k \) is generated if Eq. (8) cannot be solved for \( x_{k+1} \) using the Newton-Raphson method, or if any of the following conditions is met

\[
\|x_{k+1} - (x_c + U_c y_{k+1})\| > \varepsilon, \tag{10}
\]

\[
\|y_{k+1} - y_k\| < \cos(\alpha), \tag{11}
\]

\[
\|x_{k+1} - x_k\| > \rho, \tag{12}
\]

where \( \varepsilon, \alpha, \) and \( \rho \) are user-defined parameters. The three conditions are introduced to ensure that the chart domains \( P_c \) capture the overall shape of \( \mathcal{X} \) with sufficient detail. The first condition limits the maximal distance between the tangent space and the manifold \( \mathcal{X} \). The second condition ensures a bounded curvature in the part of the manifold covered by a local parameterization, as well as a smooth transition between charts. Finally, the third condition is introduced to ensure the generation of new charts as the RRT grows, even for (almost) flat manifolds.

**C. Chart coordination**

Since the charts will be used to generate samples, it is important to reduce the overlap between new charts and those already in the atlas. Otherwise, the areas of \( \mathcal{X} \) covered by several charts would be oversampled. To avoid so, the set of valid parameters for each chart \( c \), \( P_c \), is defined as the intersection of a ball of radius \( \sigma \) centered at the origin of \( \mathbb{R}^{d_X} \) and a number of half-planes, all defined in \( T_x \mathcal{X} \). The set \( P_c \) is progressively bounded as new neighboring charts are created around chart \( c \). If, while growing an RRT branch using the local parameterization provided by \( T_x \mathcal{X} \), a chart is created at a point \( x_k \) with parameter vector \( y_k \) in \( P_c \), then the following inequality

\[
y^\top y_k - \frac{\|y_k\|^2}{2} \leq 0 \tag{13}
\]

with \( y \in \mathbb{R}^{d_X} \), is added to the definition of \( P_c \) (Fig. 3). A similar inequality is added to \( P_k \), the chart at \( x_k \), by projecting \( x_k \) to \( T_x \mathcal{X} \). The parameter \( \sigma \) must be larger than \( \rho \) to guarantee that the RRT branches in chart \( c \) will eventually trigger the generation of new charts, i.e., to guarantee that Eq. (12) eventually holds.

**V. PLANNER IMPLEMENTATION**

Algorithm 1 gives the top-level pseudocode of the planner we propose. It can be seen that, at this level, the algorithm is almost identical to the one proposed in [6], the only difference being that we use an atlas \( \mathcal{A} \) of \( \mathcal{X} \) in our case (initialized in line 4 with one chart centered at \( x_t \) and another at \( x_g \)) to support the lower-level sampling and simulation tasks. As in [6], the algorithm implements a bidirectional RRT where one tree is extended (line 8) towards a random sample (generated in line 6) and then the other tree is extended (line 10) towards the state just added to the first tree. The process is repeated until the trees become connected with a user-specified accuracy (parameter \( \beta \) in line 12). Otherwise, the trees are swapped (line 11) and the process is repeated. Tree extensions are always initiated at the state in the tree closer to the target state (lines 7 and 9). Different metrics can be used without affecting the overall structure of the planner. As in [6], we shall use the Euclidean distance in state space for simplicity.

**Algorithm 1: The top-level pseudocode of the planner**

1. **PLANNER** (\( x_t, x_g \))
2. **input**: The query states, \( x_t \) and \( x_g \).
3. **output**: A trajectory connecting \( x_t \) and \( x_g \).
4. \( T_t \leftarrow \text{INITRRT}(x_t) \)
5. \( T_g \leftarrow \text{INITRRT}(x_g) \)
6. \( A \leftarrow \text{INITATLAS}(x_t, x_g) \)
7. repeat
8. \( x_{rand} \leftarrow \text{SAMPLE}(A, T_t) \)
9. \( x_{near} \leftarrow \text{NEARESTSTATE}(T_t, x_{rand}) \)
10. \( x_{new} \leftarrow \text{CONNECT}(A, T_t, x_{near}, x_{rand}) \)
11. \( x_{near} \leftarrow \text{NEARESTSTATE}(T_g, x_{new}) \)
12. \( A \leftarrow \text{CONNECT}(A, T_g, x_{near}, x_{new}) \)
13. \( A \leftarrow \text{SWAP}(T_t, T_g) \)
14. until \( \|x_i - x_{new}\| < \beta \)
15. **RETURN** (\( \text{TRAJECTORY}(T_t, x_{new}, T_g, x_{new}) \))

**A. Sampling**

The atlas \( A \) is key to implement the **SAMPLE** method of Algorithm 1. The procedure employed is described by Algorithm 2. Initially, one of the charts covering the tree \( T \)
is selected at random with uniform distribution (line 3). A vector \( y_{\text{rand}} \) of parameters is then randomly sampled inside a ball of radius \( \sigma \) centered at the origin of \( \mathbb{R}^d \) (line 4), repeating this sampling if necessary until \( y_{\text{rand}} \) falls inside the set \( P_c \) for the selected chart. The procedure finally returns the point \( x_{\text{rand}} = x_c + U_c y_{\text{rand}} \) corresponding to the ambient space coordinates of \( y_{\text{rand}} \) (line 7). Notice that this point lies on the tangent space \( T_{x_c} X \), instead of on \( X \), because the tangent space point is enough to steer the tree towards the unexplored regions.

Observe that, initially, the set \( P_c \) is the mentioned ball of radius \( \sigma \) centered at the origin of \( \mathbb{R}^d \). However, as new neighboring charts are successively created around a given chart (as described in Sec. IV-A), the set \( P_c \) is incrementally reduced by the addition of the limiting hyperplanes given by Eq. (13). Thus, the sets \( P_c \) of fully-surrounded charts become much smaller than the original ball of radius \( \sigma \), and their probability of being sampled decreases considerably. Charts that lie at the borders of the RRT, on the contrary, have fewer neighboring charts (and thus a larger \( P_c \) set), resulting in a higher probability of being sampled. In this way, the growing of the tree is biased towards regions outside the currently-explored state space.

### B. Tree extension

Algorithm 3 tries to connect a given state \( x_{\text{near}} \) with a goal state \( x_{\text{rand}} \). The procedure simulates the motion of the system (line 6) for a set of actions, which can be selected at random or taken from a predefined set (line 5). The action that yields a new state \( x_{\text{new}} \) closer to \( x_{\text{rand}} \) is added to the RRT with an edge connecting it to \( x_{\text{near}} \) (line 13). The action \( u_{\text{new}} \), generating the transition from \( x_{\text{near}} \) to the new state \( x_{\text{new}} \) is also stored in the tree so that an action trajectory can be returned after planning. This process is repeated as long as there is progress towards \( x_{\text{rand}} \).

Algorithm 4 summarizes the procedure used to simulate a given action, \( u \), from a particular state, \( x \). The simulation is carried out while the path is not blocked by an obstacle or by a workspace limit (line 8), while the goal state is not reached (with accuracy \( \delta \)), or for a maximum time span, \( t_m \) (line 5). At each simulation step, the key procedure is the NEXTSTATE method (line 7), which provides the next state, \( x_{k+1} \), given the current one, \( x_k \), and the action to simulate, \( u \). This is implemented by integrating Eq. (6) using local coordinates, as explained in Section IV-A. Any numerical integration method, either explicit or implicit, could be used to discretize Eq. (9). We here apply the trapezoidal rule, as it yields an implicit integrator whose computational cost (integration and projection to the manifold) is similar to the cost of using an explicit method of the same order [15]. Also, it gives more stable and accurate solutions over long time intervals. Using this rule, Eq. (9) is discretized as

\[
y_{k+1} = y_k + \frac{h}{2} U_c^\top (g(x_k, u) + g(x_{k+1}, u)),
\]

where \( h \) is the integration time step. The value \( x_{k+1} \) in Eq. (14) is unknown, but it can be obtained using Eq. (8) as

\[
F(x_{k+1}) = 0,
\]

\[
U_c^\top (x_{k+1} - x_c) - y_{k+1} = 0.
\]

Now, both Eq. (14) and Eq. (15) are combined to form

\[
F(x_{k+1}) = 0,
\]

\[
U_c^\top (x_{k+1} - x_c) - y_{k+1} = 0.
\]

where \( x_k, y_k, \) and \( x_c \) are known and \( x_{k+1} \) is the unknown to determine. Any Newton method can be used to solve this system, but the Broyden method is particularly adequate since it avoids the computation of the Jacobian of the system at each step. Potra and Yen [15] gave an approximation of this Jacobian that allows finding \( x_{k+1} \) in few iterations.

For backward integration, i.e., when extending the RRT with root at \( x_0 \), the time step \( h \) in Eq. (16) is negative. In any case, \( h \) is adjusted so that the change in parameter space, \( \|y_{k+1} - y_k\| \), is bounded by \( \delta \), with \( \delta < \rho \). This is necessary to detect the transitions between charts, which can occur either because the next state triggers the creation of a new chart (line 12), or because it is not in the part of the manifold covered by the current chart (line 14) and, thus, it is in the part covered by a neighboring chart (line 15).

**Algorithm 3: Try to connect \( x_{\text{near}} \) with \( x_{\text{rand}} \).**

1. **Connect(A, T, x_{\text{near}}, x_{\text{rand}})**
   - **input**: An atlas, \( A \), a tree, \( T \), the state from where to extend the tree, \( x_{\text{near}} \), and the random sample to be reached, \( x_{\text{rand}} \).
   - **output**: The updated tree.
   - **repeat**
     - \( d_{\text{ref}} \leftarrow \|x_{\text{near}} - x_{\text{rand}}\|\)
     - **repeat**
       - \( d_{\text{new}} \leftarrow \infty\)
       - **foreach** \( u \in U \) **do**
         - \( x \leftarrow \text{SIMULATEACTION}(A, T, x_{\text{near}}, x_{\text{rand}}, u)\)
         - \( d \leftarrow \|x - x_{\text{rand}}\|\)
         - **if** \( d < d_{\text{new}} \) **then**
           - \( x_{\text{new}} \leftarrow x\)
           - \( u_{\text{new}} \leftarrow u\)
           - \( d_{\text{new}} \leftarrow d\)
     - **if** \( x_{\text{new}} \notin T \) **then**
       - \( T \leftarrow \text{ADDACTIONSTATE}(T, x_{\text{near}}, u_{\text{new}}, x_{\text{new}})\)
     - **if** \( d_{\text{ref}} < d_{\text{new}} \) **then**
       - \( d_{\text{ref}} \leftarrow d_{\text{new}}\)
     - **until** \( d_{\text{new}} > d_{\text{ref}}\)
   - **return** \( T\)

**Algorithm 2: Generate a guiding state \( x_{\text{rand}} \).**

1. **Sample(A, T)**
   - **input**: The atlas, \( A \), the tree currently extended, \( T \).
   - **output**: A sample on the atlas.
   - **repeat**
     - \( c \leftarrow \text{RANDOMCHARTINDEX}(A, T)\)
     - \( y_{\text{rand}} \leftarrow \text{RANDOMONBALL}(\sigma)\)
     - **until** \( y_{\text{rand}} \in P_c\)
     - \( x_{\text{rand}} \leftarrow x_c + U_c y_{\text{rand}}\)
   - **return** \( x_{\text{rand}}\)
ensures that new charts summarize the problem dimensions, parameters, and performance statistics of all test cases. As the three robots involve \( n_d = 4, 5, \) and 15 joints, and each independent kinematic loop introduces 3 or 6 constraints (depending on whether the robot is planar or spatial), the dimensions of the C-space are \( d_C = 1, 2, \) and 3, respectively. The robots respectively have \( n_u = 1, 2, \) and 3 of their base joints actuated, while the remaining joints are passive. The set \( \mathcal{U} \) is discretized into a finite number of actions, which are randomly chosen at every iteration with uniform distribution between \(-\tau_{max}\) and \(\tau_{max}\).

In all test cases the parameters are set to \( t_m = 0.1, \delta = 0.05, \sigma = d_C, \rho = \sigma/2, \cos(\alpha) = 0.1, \) and \( \varepsilon = 0.1 \). Table I gives the value of \( \beta \) which, as in [6], is problem-specific. The table also shows the performance statistics on an iMac with an Intel i7 processor at 2.93 Ghz with 8 CPU cores, which are exploited to run lines 6 to 11 of Algorithm 3 equivalent to the Dextar prototype [22], but with an added spring to enhance its compliance. The goal here is to move the load from one side to the other of a wall, with null initial and final velocities. Unlike in the first case, collisions with the two walls will easily occur here, and thus they should be avoided. In the third case, a Delta robot moves a heavy load in a pick-and-place scenario, while avoiding obstacles. It picks up the load from a conveyor belt with an initial velocity, and places it at rest inside a box on a second belt. In contrast to typical Delta robot applications, here the weight of the load is considerable, which increases dynamics effects substantially.

In this paper, relative joint angles are used to formulate Eq. (5), while the Euler-Lagrange equations with multipliers are used to formulate Eq. (6).

Fig. 5. From left to right, the state manifold (in blue), and the trajectory obtained (green) for a maximum torque $\tau_{max}$ of 16, 12, 8, and 4 [Nm].

In parallel. The statistics include the number of samples and charts, as well as the planning time and the trajectory time $t_f$ in seconds, all averaged over ten runs. The planner successfully connected the starting and goal states in all runs. For the sake of comparison, we tried to solve the same test cases with the RRT method in [6], but the planner didn’t succeed in any of them.

In the case of the four-bar mechanism, results are included for decreasing values of $\tau_{max}$. As reflected in Table I, the lower the torque, the harder the planning problem. The solution trajectory on the state-space manifold (projected in one position and two velocity variables) can be seen in Fig. 5 for the different values. Clearly, the number of oscillations needed to reach the goal is successively higher. The trajectory obtained for the most restricted case is shown in Fig. 6, top.

In the five-bars robot, although it only has one more link than the previous robot, the planning problem is significantly more complex. This is due to the narrow corridor created by the obstacle to be overcome. Moreover, the motors have a severely limited torque taking into account the spring constant. In order to move the load in such conditions, the planner is forced to increase the momentum of the load before overpassing the obstacle, and to decrease it once it has passed it so as to reach the goal configuration with zero velocity (Fig. 6, middle). This increased complexity is reflected by the high ratio between the number of samples and charts. This shows that, from a given point, the planner has charted the whole of $X_{free}$ and, after that, is trying to find a way through the narrow corridor.

Finally, the table gives the same statistics for the problem on the Delta robot. The planning time is higher because the robot is spatial and it has a state space of dimension 6 in an ambient space of dimension 30. Moreover, it involves more holonomic constraints than in the previous cases, and has to avoid collisions with itself and with the environment (the conveyor belts, the boxes and the supporting structure). Also, given the velocity of the belt, the planner is forced to reduce the initial momentum of the load before it can place it inside the box (Fig. 6, bottom).

VII. CONCLUSIONS

This paper has proposed an RRT planner for dynamical systems subject to holonomic constraints. Dealing with such constraints presents two major hurdles: the generation of random samples in the state space and the driftless simulation over such space. We have seen that both issues can be addressed by relying on local parameterizations. The result is a planner that navigates the state space manifold following the vector fields defined by the dynamic constraints on such manifold. The proposed method can successfully solve significantly complex problems.

To scale to even more complex problems, several aspects of the proposed RRT planner need to be improved. Probably the main issue is the metric used to measure the distance between states. This is a general issue of all sampling-based kinodynamic planners, but in our context it is harder since the metric should not only consider the vector fields defined by the dynamic constraints, but also the curvature of the state space manifold defined by the holonomic constraints. Using a metric derived from geometric insights provided by the kinodynamic constraints might result in substantial performance improvements. Also, global optimization methods should be developed to obtain trajectories involving minimum-time or energy consumption [23], [24].
